1 Background

Flow separation is generally regarded as an unwanted phenomenon. It mainly concerns flight applications such as airplane wings and stabilizers, but affects as well other fluid dynamics applications such as ground vehicles and internal diffusers flow. When unattended, flow separation can lead to increase of drag, stall, energy losses and eventually loss of controlled flight [1]. It is therefore desirable to find methods to control this phenomenon, and if possible to avoid it - all the while not imposing a too heavy penalty such as increase in drag, energy and *etc.*

A flow-control device affects the original flow field, thus enabling modification of flow characteristics such as reduction of drag by delaying and/or eliminating separation zones. Several examples of flow-control devices include: bumps, vanes (vortex generators), synthetic jets, bleed/suction and plasma actuators.

1.1 Plasma Actuators

The interaction between the plasma and the background air can be divided to three categories [2]: momentum, shock and chemical effects. Momentum effects induce near surface flow velocities. Shock effects induce very high local gas conditions such as pressure or temperature which create gradients with the background air. Chemical effect adds new particles, such as ions, electrons, excited particles into the flow field. The most studied plasma actuator configuration is the dielectric barrier discharge (DBD) which is capable of inducing up to ~ 10 m/s flows [2, 3, 4, 5].

1.2 Cathodic Arc induced Jets

Cathodic arcs are based upon a cathode which is separated by a dielectric to an anode, coated by a ceramic surface and a resistance lowering material layer (*i.e* graphite [6]). Applying enough voltage creates a current discharge which in turn leads to emission of metallic plasma from small and mobile regions on the cathode surface.

In a recent study [6], cathodic arcs operating at atmospheric pressure environment were shown to produce fast jets of gas. It is demonstrated that a Cathodic Arc Jet (CAJ) pulse generated in an atmospheric environment, which is characterized by a time scale of hundreds of μs is capable of affecting the background still air by inducing a local flow field up to velocities of $\geq 100\text{ m/s}$. The jet direction was shown to be controlled by the application of an external magnetic field which affected the direction's rotation according to Lorentz force direction.

The results obtained in [6] suggest the possible use of a CAJ as a flow-control device, in a way similar to plasma synthetic jets. The ability to change the CAJ direction by applying an external magnetic field results in a possible usage of a CAJ as follows:

1. Enhance the turbulent mixing in order to avoid flow separation.
2. To generate transient disturbances with specific amplitude and frequencies for the excitation of instabilities.
3. To reduce the curvature of stream lines at desired locations, for example on highly loaded airfoils.

2 Objectives

The proposed research contains two main objectives:

1. The modeling of a CAJ in respect to a background flow field.
2. Characterization of the effects of a CAJ on a 2D profile in a subsonic flow.

The first objective deals with creating and evaluating an empirical CAJ model. The model should correspond well with available data from [6]. The model must deal with the flow properties of the CAJ, such as momentum, temperature, pressure and *etc.*

The second objective deals with characterization of the flow properties of a CAJ placed on a 2D profile subjected to subsonic flow, by using the model obtained in the first part of the research. The study will focus on a test case scenario of known flow over an airfoil, where control of flow separation on a NACA 0015 airfoil will be analyzed [2, 3].

3 Methodology

The research methodology is comprised of two aspects: creation of an empirical CAJ model and the application of this model in a flow field.

3.1 CAJ Model

A Cathodic-Arc-Jet empirical model will be constructed by data collected from [6]. This data-driven model will be then evaluated by comparing the simulated gas jets with the data obtained from [6]. The model will be realized as a numerical boundary condition in the flow solver.

3.2 2D Flow Field

A 2D set of Navier-Stokes equations (NS) containing the CAJ as a time lapsing boundary condition is solved.

A chosen RAS (Reynolds-Averaged Simulation) turbulent model which fits best to the evaluation test data will be used for the airfoil's flow properties study, according to the test case scenario shown in [2, 3]. Other models (*Spalart-Allmaras*, $k-\omega$ etc.) will be tested and accounted for by applying an uncertainty factor to the results. The tools used in the process are:

1. **Mesh Generation:** The numerical mesh will be generated by using Pointwise.
2. **Flow Solver:** The generated mesh will be numerically solved by using either a structured or unstructured grid solver (openFOAM/SU²/EZNSS).
3. **Flow Visualization:** The resultant flow field will be visualized by using flow visualization programs (ParaView/Tecplot) and MATLAB.
